## ABSTRACT

The unsupported NiBa catalyst has been used in the CO<sub>2</sub>-SR (CO<sub>2</sub> Storage and *in situ* Regeneration with CH<sub>4</sub>) cyclic technology, which allows the use of CO<sub>2</sub> from combustion and CH<sub>4</sub> from biogas in order to produce enriched syngas streams. The isotopic study in transient regime, using <sup>13</sup>CO<sub>2</sub> and CD<sub>4</sub> instead of <sup>12</sup>CO<sub>2</sub> and CH<sub>4</sub>, respectively, has been performed to discriminate the different carbon and hydrogen sources and the participation of the catalyst in the pathways involved in the whole cyclic process of the integrated capture of CO<sub>2</sub> and the regeneration with CH<sub>4</sub>. The dual functionality of the catalyst showed a high chemical retention capacity of CO<sub>2</sub> (around 0.15 mmol CO<sub>2</sub>·g<sub>cat</sub><sup>-1</sup>) in basic Ni-Ba intermetallic centers together with the regeneration capacity through the injection of methane yielding to H<sub>2</sub>-containing stream production. During the storage stage, the CO<sub>2</sub> adsorption and dissociative decomposition are the main reactions together with Boudouard reaction, whereas in the regeneration step, syngas was formed via chemical CO<sub>2</sub> reduction by CH<sub>4</sub>, besides dry methane reforming.

## 1. Introduction

Carbon dioxide concentration in the atmosphere has been constantly increasing as a consequence of human activities and is considerably contributing to climate change, as the main component of greenhouse gases (GHG), followed by methane. Besides, CO<sub>2</sub> emissions represent the 81 % of total GHG with the transport and the electricity generation sectors currently making the greatest contribution, with almost 60 % of total emissions [1]. Despite the current climate action headed by the nations and the goals stated in the Paris Agreement, the level of atmospheric CO<sub>2</sub> continues rising at an alarming rate. The International Energy Agency, in World Energy Outlook 2019 Report, predicted a growth in the energy demand of 1.3 % per year until 2040 if the actual energy policies do not change (Current Policies Scenario). Although, the 2020 report proposed a slight decrease derived from the Covid-19 crisis depending on the duration of the pandemic and its economic and social impact, which caused an annual drop of 5 % in world energy demand [2–4], 2021 report estimated a rebound by 1.2 % (400 MtCO<sub>2</sub>) below 2019 emissions levels because this increase of consumption. The electricity consumption is expected to increase at a higher rate respect to the

demand of energy supply, driven by the utilization of industrial and vehicle electric engines and residential use. Even renewables have been accelerated (8 % between 2020 and 2021) which are destined to become the largest source of electricity generation in the world by 2025 and met 45 % of global electricity demand growth, coal and gas-fired power generation also increased approximately 4.5 % [4]. Regardless of the decrease of energy demand derived from Covid-crisis, the increase of renewable energies versus oil and coal was clear. All efforts are focused on the reduction of CO<sub>2</sub> from energy consumption. In this sense, different strategies have been considered to decrease the emissions from current gas and coal power plants, including Carbon Capture, Utilization and Storage (CCUS), or biomass co-fired devices; to repurpose them to focus on providing system adequacy and flexibility while reducing operations; or to retire them early.

Carbon Capture and Storage (CCS) is the most mature technology for CO<sub>2</sub> depletion. CO<sub>2</sub> capture at high temperature (greater than 500 °C) results attractive for industrial applications, due to the possibility of direct operation with the combustion gases, avoiding additional cooling steps. Main drawbacks for this technology are the regeneration of these types of compounds since decarbonation reaction yield CO<sub>2</sub>-enriched

gas streams [5–9].

To face some of these limitations, a new technology based on Dual Function Materials was proposed, where a single material can capture the CO<sub>2</sub> and regenerate through a type of chemical loop, allowing the reduction of operation, transport, and storage costs, as the CO<sub>2</sub> is converted in situ into molecules of interest. Farrauto's group introduced this concept by reporting a Ru-based methanation catalyst and nano dispersed CaO as CO<sub>2</sub> adsorbent, both supported on a porous  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> carrier [10]. In this sense, the strategy of CO<sub>2</sub> revalorization into syngas using CH<sub>4</sub>, as the second most harmful gas in the atmosphere, via dry reforming (DRM) could be another alternative for the simultaneous reduction of two GHG emission.

Nickel has been recurrently used for CO<sub>2</sub> conversion [11,12], several factors have determined its wide application: its high activity, its abundance and its relative low cost, compared to other metals. Tian et al. [13] used Ni in a calcium-looping methane reforming process using a CaO-Ni bifunctional sorbent-catalyst. First, CO<sub>2</sub> is captured by reacting with CaO adsorbent to form CaCO<sub>3</sub>, then this is decomposed to bring CO<sub>2</sub> to the CaO-Ni interface for the reaction with CH<sub>4</sub> (dry reforming) to produce syngas according to the following equation:

Furthermore, similar systems for cyclic CO<sub>2</sub>-storage/conversion have been reported in the literature, including CO<sub>2</sub> storage and hydrogenation to CH<sub>4</sub> [14–17] and tri-reforming of methane for syngas production [18–20].

However, the major challenge for the CaO-based sorbents and the Ni-based catalysts is the fast decay of CO<sub>2</sub> capture performance and the deactivation of catalytic performance with the number of cycles, respectively [21]. Other investigations reported an improved activity by the incorporation of other components to the catalytic formulation, such as CeO<sub>2</sub> or Ru. The introduction of CeO<sub>2</sub> acting as a support to improve the catalytic activity has been studied extensively for the development of Ni-based catalysts [22]. Ruthenium has unique redox properties that allow it to rapidly reduce to its catalytically active state after exposure to an oxidizing environment (such as power plant flue gas) during the CO<sub>2</sub> capture step [14].

The development of advanced materials able to efficiently capture CO<sub>2</sub> and convert it into valuable chemicals (using a cyclic alternated technology based in LNT-NO<sub>x</sub> catalytic system) represents a very interesting challenge.

Recently, Molina-Ramírez et al. [23] proposed a new Catalytic Technology (CO<sub>2</sub>-SR: CO<sub>2</sub> Storage and in situ Regeneration with CH<sub>4</sub>) for CO<sub>2</sub> depletion and H<sub>2</sub> production based on the dual-function concept. In this case, an unsupported Ni-Ba bimetallic catalyst operates in an alternating cyclic isothermally regime with consecutive pulses of CO<sub>2</sub> (storage steps) and CH<sub>4</sub> (regeneration steps), producing H<sub>2</sub>-enriched streams, with a wide range of application in the energy and industry sector. Therefore, through an isotopic study, this work aims to go deep insight into the reactions involved in the two-step storage and regeneration process. The utilization of labelled molecules: <sup>13</sup>CO<sub>2</sub> and CD<sub>4</sub> instead of <sup>12</sup>CO<sub>2</sub> and CH<sub>4</sub> would allow to discriminate the different carbon and hydrogen sources and the participation of the catalyst in the whole cyclic process of CO<sub>2</sub> storage and CH<sub>4</sub> regeneration.

## 2. Experimental

### 2.1. Catalyst synthesis

An unsupported Ni-Ba bimetallic catalyst was synthesized with a Ni/Ba atomic ratio = 1/1 by coprecipitation of Ni(NO<sub>3</sub>)<sub>2</sub>·6H<sub>2</sub>O and Ba(NO<sub>3</sub>)<sub>2</sub> precursors (Panreac Applichem). A 3 wt% of total mass of atoms of colloidal silica was added (referred to Ni and Ba atomic content in the precursor solution). LUDOX HS-40 colloidal silica was purchased from Aldrich Chemistry (40 wt% SiO<sub>2</sub> in H<sub>2</sub>O, surface area 198–258 m<sup>2</sup>/g), as

a surface area promoting and nucleation agent. Then, the generated gel was washed, dried for 24 h at 80 °C, and calcined at 800 °C (5 °C·min<sup>-1</sup>) in air for 4 h. XRD X-ray Powder Diffraction data obtained with an X'Pert Pro MPD diffractometer (PANanalytical) using a CuK<sub>α1</sub> radiation ( $\lambda = 1.5406 \text{ \AA}$ ) and a Ge(1 1 1) primary monochromator are included. Further details of preparation and characterization were early reported by Molina-Ramírez et al. [23].

### 2.2. Catalytic test and isotopic experiments

Catalytic cyclic tests for CO<sub>2</sub> Storage and Regeneration with CH<sub>4</sub> were performed isothermally at atmospheric pressure, using Transient Response Method (TRM) in a “U-shaped” quartz fixed-bed reactor (d<sub>i</sub> = 6 mm) with down-flow connected to a QMS 200 mass spectrometer (Pfeiffer Vacuum Prisma<sup>TM</sup>). In each experiment, 60 mg of NiBa catalyst were used, maintaining a total inlet flow gas of 50 mL·min<sup>-1</sup> and a space velocity GHSV of 1 0.06·10<sup>4</sup>h<sup>-1</sup>. Inlet gases were fed at reactor with flow mass controllers (PID-flow controller) attached to a motorized valve that allowed instantaneous feed changes in the supply. Prior to each experiment, the catalyst was reduced *ex situ* in 20 %H<sub>2</sub>-He atmosphere for 2 h at 600 °C and was conditioned in situ in He up to 600 °C, and then activated in a He-balanced H<sub>2</sub> stream (2 %H<sub>2</sub>-He, 50 mL·min<sup>-1</sup>) for 1 h, followed by He purge until all signals reach baseline.

Three different experiment-set were performed as it is represented in Fig. 1: Type I runs, consisting of alternated cycles of CO<sub>2</sub>-He-CH<sub>4</sub>, Type II runs, consisting of alternated cycles with labelled-C, <sup>13</sup>CO<sub>2</sub>-He-CH<sub>4</sub> and Type III runs, consisting of alternated cycles with labelled H, CO<sub>2</sub>-He-CD<sub>4</sub>. More specifically, pulses of 5 min of each gas reagent (10,000 ppm of CO<sub>2</sub> for storage step and CH<sub>4</sub> for regeneration one diluted in He) were alternated with a He-purge of 15 min; this allowed the stabilization of all m·z<sup>-1</sup> signals after the previous pulse using Argon as a tracer.

The same experimental set was performed at 600, 650 and 700 °C, in order to evaluate the temperature effect. Outlet gases were analyzed with a mass spectrometer and the studied m·z<sup>-1</sup> signals were: 2 (H<sub>2</sub>), 3 (D<sub>2</sub>), 4 (He), 12 (C), 13 (<sup>13</sup>C), 14 (N), 16 (CH<sub>4</sub>), 17 (H<sub>2</sub>O), 19 (D<sub>2</sub>O), 20 (CD<sub>4</sub>), 28 (CO), 29 (<sup>13</sup>CO), 32 (O<sub>2</sub>), 40 (Ar), 44 (CO<sub>2</sub>) and 45 (<sup>13</sup>CO<sub>2</sub>). These signals were selected in order to avoid any influence between the species and were normalized and most of them are calibrated. In all cases Ar was used as a tracer. Before running each type of experiment, a test without catalyst was performed, and the recorded mass spectrometry (MS) lines were used as a blank. Moreover, all the signals were normalized respect to its maximum intensity during each experiment.

In previous works [23], it was demonstrated that during the storage step, CO<sub>2</sub> can be stored or converted whereas in the regeneration step CH<sub>4</sub> was only converted. For that, the equations and notation to describe the conversion of each reagent was different and it is indicated in Eqs. (2) – (5).

$$\%CO_2^{sto+conv} = \frac{F_{CO_2}^{stored+converted}}{F_{CO_2}^{in}} \cdot 100 = \frac{F_{CO_2}^{in} - F_{CO_2}^{out}}{F_{CO_2}^{in}} \cdot 100 \quad (2)$$

$$\%^{13}CO_2^{sto+conv} = \frac{F_{CO_2}^{stored+converted}}{F_{^{13}CO_2}^{in}} \cdot 100 = \frac{F_{^{13}CO_2}^{in} - F_{^{13}CO_2}^{out}}{F_{^{13}CO_2}^{in}} \cdot 100 \quad (3)$$

$$\%CH_4^{conv} = \frac{F_{CH_4}^{converted}}{F_{CH_4}^{in}} \cdot 100 = \frac{F_{CH_4}^{in} - F_{CH_4}^{out}}{F_{CH_4}^{in}} \cdot 100 \quad (4)$$

$$\%CD_4^{conv} = \frac{F_{CD_4}^{converted}}{F_{CD_4}^{in}} \cdot 100 = \frac{F_{CD_4}^{in} - F_{CD_4}^{out}}{F_{CD_4}^{in}} \cdot 100 \quad (5)$$

Where F represents the flow equivalent in terms of area obtained from the integration of MS responses of CO<sub>2</sub> or <sup>13</sup>CO<sub>2</sub> and CH<sub>4</sub> or CD<sub>4</sub> registered during storage and regeneration steps, respectively, extended almost for 10 alternating cycles. Each value was calculated from the third operation cycle in each experiment.

**Fig. 1.** Experimental set-up of the non-isotopic and isotopic runs performed to analyze the performance of NiBa catalyst in the CO<sub>2</sub>-SR cyclic technology at any temperature. Reaction conditions: 50 mL·min<sup>-1</sup>, GHSV of 1.06·10<sup>4</sup>h<sup>-1</sup>.

### 3. Results and discussion

It was stated that the NiBa catalyst is able to maintain its structure at high temperatures with a high reducibility even as bulk catalyst and presented well-balanced and distributed strong basic sites. XRD patterns and Raman spectra were previously published [23] for the NiBa catalyst calcined at 800 °C and reduced at 600 °C. For comparative purposes, in Fig. S1.a X-ray Diffractograms for the samples activated in hydrogen at 650 and 700 °C are represented and, however, Raman spectra of these samples are not included since there are no differences with the spectra obtained for the sample reduced at 600 °C. The disappearance of signals related to NiO and the identification of peaks associated with Ni<sup>0</sup> was confirmed at all the reduction temperatures. Crystallite size was calculated by Debye-Scherrer equation and the value was kept around 10 to 15 nm for all the samples reduced between 600 and 700 °C. A small amount of Ba can be found as BaCO<sub>3</sub> and Ba<sub>2</sub>SiO<sub>4</sub> species that are not active in the process, whereas BaO was not observable by XRD and Raman. There is an effect of BaO on Ni particle species dispersion control

because BaO interacts with Ni particles, since species where all the elements are well-distributed are observed (Fig S1.b). For the catalyst reduced at different temperature, the plausible formation of BaO-Ni nanointerphases exists, as was reported [23], where BaO interact with Ni species at surface level providing CO<sub>2</sub>-chemi-adsorption sites that are even capable of carbon oxidation.

#### 3.1. Type I runs for experiment validation

A set of experiments with non-labelled molecules was carried out as a catalytic test reference under isothermal transient regime using CO<sub>2</sub>-He-CH<sub>4</sub> pulses (10,000 ppm feed gases as rectangular pulse). In Fig. 2 the CO<sub>2</sub> storage and regeneration mass spectrometer signal profiles for five CO<sub>2</sub>-He-CH<sub>4</sub> consecutive cycles at 700 °C are shown.

Carbon monoxide and hydrogen signals along with the CO<sub>2</sub> fed were monitored and detected during CO<sub>2</sub> storage step, whereas CH<sub>4</sub>, H<sub>2</sub>, and CO were registered during the regeneration step (CH<sub>4</sub> pulse). The ion-current H<sub>2</sub>O-signal appear to be perturbed during the whole

**Fig. 2.** H<sub>2</sub>, CH<sub>4</sub>, CO, CO<sub>2</sub> mass signals during CO<sub>2</sub>-He-CH<sub>4</sub> alternating cycles (Type I runs) at 700 °C. Reaction conditions: 50 mL·min<sup>-1</sup>, GHSV of 1.06·10<sup>4</sup>h<sup>-1</sup>.

experiment and unfortunately, the peak-shape was not well-defined inside of pulse-width and consequently was not included in the figures. It must be pointed out that the intensity of all the registered signals decreased during the He purge period, reaching values near zero, indicating a catalyst surface free of weakly-adsorbed molecules. The system reached a stable regime after three storage and regeneration cycles, near 80 min after the admission of CO<sub>2</sub> pulse, as the CO and H<sub>2</sub> signal profiles became comparable over the consecutive pulses until the end of the experiment.

To evaluate the performance, the outlet gas signal distribution registered during the storage and regeneration steps for the third cycle of Type I runs (CO<sub>2</sub>-He-CH<sub>4</sub>) at 700 °C was depicted in Fig. 3. Moreover, the profiles obtained at 600 and 650 °C can be found in supplementary information (Figure S2). During the storage-step, mass-signals corresponding to CO<sub>2</sub>, CO, and H<sub>2</sub> were principally detected. The increase of the (*m*-*z*<sup>-1</sup> = 44) signal after the CO<sub>2</sub> injection is not instantaneous but progressive, yielding as the CO<sub>2</sub>-breakthrough curve.

This CO<sub>2</sub> sigmoidal curve-shaped profile was related to the adsorption of CO<sub>2</sub> chemically bonded over the catalyst-surface resulting a useful storage capacity, whose values were estimated from the first cycle after H<sub>2</sub>-reduction of catalyst and are shown in Table 1.

At 600 °C the CO<sub>2</sub> retention capacity was 0.6 % (0.126 mmolCO<sub>2</sub>·g<sub>cat</sub><sup>-1</sup>) by weight of catalyst (adsorbed CO<sub>2</sub> mass/catalyst weight in percentage). The net CO<sub>2</sub> adsorption capacity continuously increased with temperature, reaching a maximum of 0.8 % (wt.) of CO<sub>2</sub> at 700 °C, the maximum tested temperature. The evolution of the CO<sub>2</sub> storage capacity depends on the temperature and a slight strengthening of the basic sites was proven. As was reported by A. Bermejo-Lopez et al. [24] using Al<sub>2</sub>O<sub>3</sub> supported Ni-CaO catalyst a maximum CO<sub>2</sub> storage capacity around 520 °C was registered close to 0.17 mmolCO<sub>2</sub>·g<sub>cat</sub><sup>-1</sup>, because the carbonated formed onto the alkaline-earth oxides present a high stability. The increase in temperature favors a deeper activation of the basic sites that promotes a higher CO<sub>2</sub> adsorption.

In the CO<sub>2</sub>-step, mainly CO and H<sub>2</sub> signals were rapidly evolved. It is clearly noticeable that the hydrogen trace presented is due to the previous CH<sub>4</sub>-step since it is absent in the first cycle. After that, the feed switched to He purge for 15 min. Subsequently, as regeneration-phase, CH<sub>4</sub> was injected into the system, and H<sub>2</sub>, and CO were observed, together with the superimposed CH<sub>4</sub> signal, with a fast increased initially followed by a tail-end signal similar to that observed during the CO<sub>2</sub> storage phase. The intensity of the CH<sub>4</sub> signal progressively increases until saturation but, during this step, CH<sub>4</sub> was not stored but mainly reacts with the surface stored species to be converted to other molecules.

The calculated value CO<sub>2</sub><sup>sto+conv</sup> (i.e., stored and converted) during

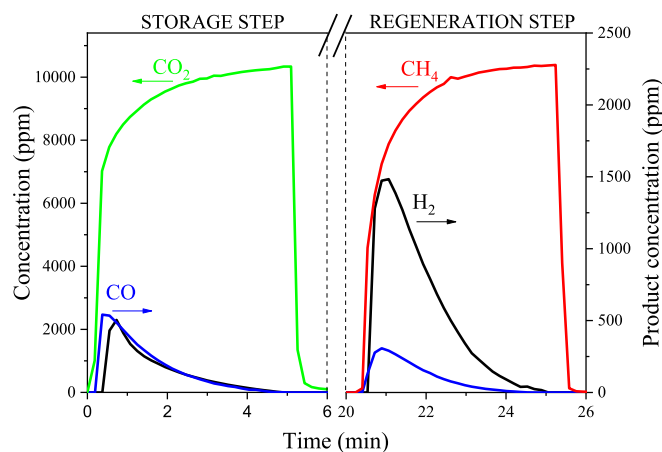

Fig. 3. Outlet gas signal distribution registered during the storage and regeneration steps for the third cycle of Type I runs (CO<sub>2</sub>-He-CH<sub>4</sub>) at 700 °C. Reaction conditions: 50 mL·min<sup>-1</sup>, GHSV of 1.06·10<sup>4</sup>h<sup>-1</sup>.

Table 1

Adsorption capacity, conversion and selectivity ratio for Type I runs at different temperatures.

Temperature (°C)	Adsorption Capacity* (mmol CO <sub>2</sub> ·g <sub>cat</sub> <sup>-1</sup> )	CO <sub>2</sub> <sup>sto+conv</sup> (%)**	CO/H <sub>2</sub> **	CH <sub>4</sub> <sup>conv</sup> (%)***	H <sub>2</sub> /CO***
600	0.126	8.18	2.35	14.52	25.45
650	0.142	8.51	1.48	19.14	8.17
700	0.183	9.21	1.21	20.19	5.31

\*From the first cycle of CO<sub>2</sub>-adsorption after reduction.

\*\*From stable storage step.

\*\*\* From stable regeneration step.

the storage period was 9.2 % at 700 °C. For the regeneration period, CH<sub>4</sub><sup>conv</sup> reached a value of 20.2 % and H<sub>2</sub>/CO molar ratio of 5.3. These values are very far from the reported equilibrium conversion values at 700 °C for CO<sub>2</sub> and CH<sub>4</sub> (near 90 %, with CO<sub>2</sub> value slightly higher) when a CO<sub>2</sub>/CH<sub>4</sub> = 1 ratio is co-fed, since in this work the reactants are fed separately under a discontinuous pulse feeding system (transitory regime). Besides, it should be considered that the material presented a relatively low CO<sub>2</sub> retention capacity and methane conversion was higher than CO<sub>2</sub> conversion values, due to side reactions that takes place during the regeneration step that increase methane conversion, such as methane decomposition as was reported in [23]. In our previous work [25], the results of dry catalytic reforming under transient experiment for a model Pt/Al<sub>2</sub>O<sub>3</sub> type catalysts were reported and the CO<sub>2</sub> conversion values were systematically above the CH<sub>4</sub> conversion calculated values (47 and 36 % respectively). These differences could be in part due to the experimental procedure in which CH<sub>4</sub> and CO<sub>2</sub> are co-fed, and the type and functionality of catalysts which also activate CO<sub>2</sub> molecule instead of storing it.

The saturation curves for CO<sub>2</sub> and CH<sub>4</sub>, in the storage and regeneration stages, respectively, have the same shape but the conversion estimated values of the reactants are different. For methane conversion, there is an increase with temperature, starting from 14.52 % at the lowest tested temperature, and the amount of CO<sub>2</sub> stored and converted also increase with temperature, varying from 8.18 to 9.21 %, as can be observed in Table 1. During the storage and regeneration periods both CO and H<sub>2</sub> appear. In the storage stage, as the CO/H<sub>2</sub> molar ratio is higher than 1, it suggests that the predominant reaction should be the formation of CO. During the regeneration stage, the H<sub>2</sub>/CO molar ratio is higher than 1 and higher than the stoichiometric ratio of the reforming, indicating the occurrence of a hydrogen production process that is favoured by temperature. Although hydrogen production increases with temperature, H<sub>2</sub>/CO ratio decreases from 25.5 to 5.3 because the amount of CO formed increases in a higher proportion, indicating a more pronounced effect of the temperature in the reactions that include CO production.

In a first approximation based on this type of experiments, the reactions that must be involved in the CO<sub>2</sub>-SR technology are:

Storage stage

Regeneration stage

### 3.2. Isotopic Type II and III experiments

The utilization of  $^{13}\text{CO}_2$  and  $\text{CD}_4$  as alternative carbon and hydrogen sources in Type II and III experiments, respectively, was an additional tool in order to understand the main reactions occurring in this  $\text{CO}_2$ -SR Cyclic Process over unsupported NiBa catalyst.

In Fig. 4, the product distribution during storage and regeneration phases corresponding to Type II experiment ( $^{13}\text{CO}_2$ -He- $\text{CH}_4$ ) at  $650^\circ\text{C}$  is presented. Although no  $\text{CO}_2$  neither  $\text{CH}_4$   $\text{m}\cdot\text{z}^{-1}$  signals were represented, Ar does, so the start of each step of the cycle is indicated in the figure. The reagent and product profiles at all the tested temperatures can be found in Fig. S3. The Ni-BaO catalytic performance in terms of  $\text{CO}_2^{\text{sto}+\text{conv}}$  and  $\text{CH}_4^{\text{conv}}$  values registered at  $650^\circ\text{C}$  were 9.1 % and 16.4 %, respectively, similar to the data obtained in type I runs. In the storage stage, a CO sharp-signal formation is detected first and, with delay of several seconds,  $^{13}\text{CO}$  is also detected. At all temperatures, the time-response and the  $^{13}\text{CO}$  and CO profiles indicate the formation of these species preferentially during the storage step. In addition, a  $\text{H}_2$ -signal delay was also observed associated with  $\text{H}_2$ -chemisorbed release involving nickel sites or the gasification of carbon with hydroxylated centers. The instantaneous formation of unlabeled CO is related to the fact that gas  $^{13}\text{CO}_2$  reacts directly with the deposited carbon (C(s)) species to give two molecules of labeled and unlabeled CO [Eq. (11)] [26]. Given that the calculated  $^{13}\text{CO}/\text{CO}$  ratio is higher than 1, a parallel reaction associated with the dissociative decomposition reaction of the  $^{13}\text{CO}_2$  fed occurs [Eq.12], at the basic sites of the catalyst, in agreement with the results obtained by other authors [27,28] working in a simultaneous feed of labeled  $\text{CO}_2$  and  $\text{CH}_4$ . The release of the sites occupied by the adsorbed carbon allows the dissociative decomposition of the fed  $\text{CO}_2$  and produces the delay in the maximum formation of labeled CO. Although the system is working in dry conditions C(s) could also react via gasification with hydroxylated surface (water from the regeneration step) [Eq.13], generating additional  $\text{CO}(\text{g})$  and  $\text{H}_2(\text{g})$  and this can explain the delayed hydrogen formation. Occasionally, the hydrogen formed could react with  $\text{CO}_2$  through the reverse of Water Gas Shift [Eq.14], although the contribution of this reaction would be minor in this stage.

Fig. 4. Product distribution registered during the storage and regeneration steps for the third cycle of Type II runs ( $^{13}\text{CO}_2$ -He- $\text{CH}_4$ ) at  $650^\circ\text{C}$ . Reaction conditions:  $50 \text{ mL}\cdot\text{min}^{-1}$ , GHSV of  $1.06\cdot 10^4 \text{ h}^{-1}$ .

In the regeneration phase, by injecting a rectangular pulse of 10,000 ppm  $\text{CH}_4$  after the  $^{13}\text{CO}_2$  pulse, the formation of hydrogen was evidenced as a result of the catalytic methane decomposition with C(s) production, pointing out that methane activation in successive  $\text{CH}_x$  steps occurs over Ni-sites [Eq.15], as a well-known mechanism. In addition, the observing breakthrough signals of  $^{13}\text{CO}$  and unlabeled CO in the regeneration phase suggests that the formation pathway, of these molecular species, come from methane reforming with  $^{13}\text{CO}_2$  (ads) [Eqs. (16) and (17)]. For the conventional dry reforming reaction, the limiting step in the process is methane activation. However, on a surface partially enriched in  $\text{CO}_2$  via carbonate formation, which occurs during the  $\text{CO}_2$  storage stage, it cannot be ruled out that there is a fraction of  $\text{CH}_4$  in the gas phase that can react with the  $\text{CO}_2$  species stored on the catalyst surface, by chemical reduction and regeneration with the formation of syngas [Eq. (16)], in the named  $\text{CO}_2$ -storage and  $\text{CH}_4$  regeneration reaction. Besides, the activation of both  $\text{CO}_2$  and  $\text{CH}_4$  occurs on the metal sites as a bifunctional mechanism, so  $\text{CH}_4$  reacts directly from gas phase as commented above or via the activation on the metal surface giving  $\text{CH}_x$  (cat), forming syngas as conventional dry reforming mechanism [Eq. (17)]. It must be pointed out that due to the cyclic configuration used here, by the time  $\text{CH}_4(\text{g})$  was injected,  $\text{CO}_2^{\text{sto}}$  was already adsorbed on the catalyst in form of carbonate species, avoiding the kinetic limitations associated with the  $\text{CO}_2$  adsorption process. Since the CO-proportion content,  $^{13}\text{CO}/\text{CO}$  ratio, is close to 0.20, the amount of CO detected at the outlet during the whole pulse is higher than the labelled molecule. This production comes from the oxidation of the  $\text{CH}_x$  species with the  $\text{O}^*$  species from  $^{13}\text{CO}_2$  decomposition [27] to form CO as consecutive reaction [Eq. (17)], and even this CO could also react with another dissociated  $\text{O}^*$  to form newly  $\text{CO}_2$  [Eq. (18)].

The influence of temperature in the reactions described above was evaluated, so, in Fig. 5, CO and  $^{13}\text{CO}$  lines during storage and regeneration steps at 600, 650,  $700^\circ\text{C}$  were showed. During the storage pulse, the maximum intensity of the sharp unlabeled CO signals increases appreciably with temperature, and the broad and asymmetric  $^{13}\text{CO}$  signals are three times less intense than those of unlabeled CO, however, the trend is kept with the temperature increases. The  $^{13}\text{CO}/\text{CO}$  ratio remains higher than 1, although this ratio depends on the temperature,

Fig. 5. CO and  $^{13}\text{CO}$  mass signals during the storage and regeneration steps for the third cycle of Type II runs ( $^{13}\text{CO}_2$ -He- $\text{CH}_4$ ) at 600, 650,  $700^\circ\text{C}$ . Reaction conditions:  $50 \text{ mL}\cdot\text{min}^{-1}$ , GHSV of  $1.06\cdot 10^4 \text{ h}^{-1}$ .

varying from 1.50 to 1.38 at increasing temperature. Quantitatively, and in terms of mmol of CO formed during the storage cycle, estimated from the area under the curve, the increase in the amount of  $^{13}\text{CO}$  produced with temperature is confirmed, varying between 0.5, 0.7 and 1.1  $\mu\text{mol}$  per cycle between 600, 650 and 700  $^{\circ}\text{C}$ , respectively. Similarly, the values recorded for unlabeled CO vary between 0.3  $\mu\text{mol}$  at the lowest temperature tested and remain at approximate values of 0.6  $\mu\text{mol}$  at temperatures greater than 650  $^{\circ}\text{C}$ . The linear trend in  $^{13}\text{CO}$  production to increase with temperature is a direct consequence of dissociative adsorption and storage of  $^{13}\text{CO}_2$  on the catalyst. On the other hand, the asymptotic trend around a value of 6  $\mu\text{mol}$  of unlabelled CO indicates that the extent of the CO production reaction by gasification of the carbon formed on the catalyst surface [Eq. (11)] is limited by the amount of carbon deposited on the surface.

During regeneration, the amount of CO produced is an order of magnitude lower than that registered during the storage period, the  $\text{CO}/^{13}\text{CO}$  ratio is higher than 1 and the intensity of both CO and  $^{13}\text{CO}$  signals increased with temperature, evidencing the positive effect of temperature on endothermic reactions [29] and the higher methane conversion. A higher influence of temperature on the CO signal with respect to that of  $^{13}\text{CO}$  has been observed, due to an increase of temperature favours the reaction [Eq. (17)] involving the activated methane ( $\text{CH}_x(\text{cat})$ ). The increase in the overall activity in this step is related to a higher population of active Ni-Ba species able to activate fed methane.

In order to study the reactions involved during the regeneration step and elucidate the hydrogen source during the storage step, methane was substituted by  $\text{CD}_4$  in Type III runs. In Fig. 6, the product distribution registered during the storage and regeneration steps for the third cycle ( $\text{CO}_2\text{-He-CD}_4$ ) at 600, 650 and 700  $^{\circ}\text{C}$  is represented. Additionally, in Supplementary Information (Fig. S4) the profiles of  $\text{CO}_2$  and  $\text{CD}_4$  together with CO and  $\text{D}_2$  are also included at all tested temperatures. During the storage step, CO profiles were similar to those obtained in Type I experiments and the sum of CO and  $^{13}\text{CO}$  in Type II runs. In addition, no significant changes are detected in the signals assigned to deuterium and  $\text{H}_2$ , indicating that the formation of hydrogen observed in type I and II experiments would be related to the intervention of surface OH species connected to Barium sites due to the water formed in the regeneration stage and represented as  $\text{H}_2\text{O}(\text{ads})$  in Eq. (13). In the regeneration step, CO and  $\text{D}_2$  were the detected products, being the former similar in shape to the profiles registered for experiments with unlabeled methane but slightly decreasing the overall production. On the other hand, a sharp  $\text{D}_2$  signal was recorded with an intensity-one order of magnitude lower than that of hydrogen (compared in Fig. S5), which can be associated with a lower  $\text{m}\cdot\text{z}^{-1}$  signal response at the same concentration or with the lower reduction capacity of the

labeled methane. As can be observed, the production of all products increases with temperature in the same line that what has been previously detailed for Type I and II runs. Nevertheless, it is noteworthy that the conversion values of the reagents ( $\text{CO}_2$  and  $\text{CD}_4$ ) and the production of CO and  $\text{D}_2$  were slightly lower than those of the experiments without labeled  $\text{CH}_4$ . These observations are in consonance with the effect registered by other authors when  $\text{CH}_4$  is replaced by  $\text{CD}_4$ . A decrease in  $\text{CD}_4$  conversion was detected in the methane oxidation [30] or in methane reforming with Ni-based catalysts [31–33], which can be related to a decrease in the CO formation rate and due to a low isotope effect.

According to these results, in the regeneration step,  $\text{CD}_{4(\text{g})}$  molecules react with the  $\text{CO}_2$  retained during the previous storage step, generating  $\text{D}_{2(\text{g})}$  and  $\text{CO}_{(\text{g})}$  via Dry Reforming of isotopic Methane [Eq. (19)]. Moreover, the catalytic  $\text{CD}_{4(\text{cat})}$  decomposition [Eq. (20)] would provide more  $\text{D}_{2(\text{g})}$  and  $\text{C}(\text{s})$ , and the  $\text{CD}_x$  species necessary for the reaction with  $\text{CO}_2$  in the dry reforming process [34] that react with the surface oxygen species to produce a higher amount of CO and  $\text{D}_2$  [Eq. (21)].

Isotopic tracer study led us to corroborate a simple and rigorous mechanistic picture of the reaction network during alternating cycles and how Ni-clusters linked to BaO species on the catalyst surface favored the pathways of both  $\text{CO}_2$  dissociation (activation) and CO formation by the reverse Boudouard reaction during the storage phase (caused by the interaction of dissociated  $\text{CO}_2$  species and deposited carbon species) and the  $\text{CH}_4$  decomposition process and catalytic reforming reactions involved along the regeneration phase, explaining the formation of the molecular species recorded. The percentage of  $\text{CO}_2$ -stored + converted and  $\text{CH}_4$ -conversion average values on Type I, II, and III runs are shown in Fig. 7, and were calculated from numerical integration of the  $\text{CO}_2/^{13}\text{CO}_2$  or  $\text{CH}_4/\text{CD}_4$  lines during storage and regeneration steps, respectively. Data were calculated from the third cycle, where a stable regime was reached. The conversion values at a given temperature were similar in all type runs, evidencing the reproducibility of the three types of experiments regardless of the kind of molecules injected. Nevertheless, the deviation in  $\text{CH}_4/\text{CD}_4$  conversion values is around 4 % and higher than the values calculated for  $\text{CO}_2$ , which are lower than 1 %. This fact can be explained because of the kinetic isotope effect [35,36] that is referred to the effect on the reaction rate due to the isotopic

Fig. 6. Product distribution registered during the storage and regeneration steps for the third cycle of Type III runs ( $\text{CO}_2\text{-He-CD}_4$ ) at 600, 650 and 700  $^{\circ}\text{C}$ . Reaction conditions:  $50 \text{ mL}\cdot\text{min}^{-1}$ , GHSV of  $1.06\cdot 10^4 \text{ h}^{-1}$ .

Fig. 7. Conversion mean values of the amount of  $\text{CO}_2$  or  $^{13}\text{CO}_2$  stored and converted and  $\text{CH}_4$  or  $\text{CD}_4$  converted values at 600, 650 and 700  $^{\circ}\text{C}$ . Reaction conditions:  $50 \text{ mL}\cdot\text{min}^{-1}$ , GHSV of  $1.06\cdot 10^4 \text{ h}^{-1}$ .

replacement of one or more bonds of the reactant. More specifically, when isotopic exchange refers to the replacement of hydrogen with deuterium, the properties of the bond are significantly affected. So, for the cleavage of a C-D bond, higher energy is required with respect to that for the C-H bond, producing the slight decrease in methane conversion.

### 3.3. Description of the CO<sub>2</sub>-SR cyclic process

The study of the distribution of products in cyclic experiments and the use of isotopic molecules have allowed to establish the reactions involved in the CO<sub>2</sub>-SR process. The NiBa unsupported catalyst has a dual function that requires centers capable of retaining CO<sub>2</sub> in the storage stage and other suitable sites that perform catalyst regeneration. In addition, the developed and potentially upgradeable Ni-Ba unsupported catalyst has shown a suitable performance. The presence of an alkaline-earth element in form of barium oxide is linked to the adsorption role during the storage stage due to the basic-site distribution. The presence of Ni metallic species ensures methane activation for the catalyst regeneration via chemical reduction. An interaction (Ni.BaO) has to exist that prevent sintering and limit the formation of spectator or catalytically inactive species. Furthermore, BaO increases the electron cloud density of Ni and the performance at a high reaction temperature range is also attributed to the highest amount of oxygen vacancies and Ni<sup>0</sup> stable centers on the catalyst surface as was reported previously [23].

Through the analysis of the product distribution obtained from isotopic and non-isotopic runs, a reaction process scheme was proposed and represented in Fig. 8. CO<sub>2</sub>-SR technology utilizes a Ni-Ba unsupported catalyst, feeding CO<sub>2</sub>, which is contained in the composition of a combustion gas-off, and methane, as one of two main components of biogas, during the storage and regeneration steps, respectively. During the storage step fed CO<sub>2</sub> is stored as labile carbonates on strong Ba-basic sites (identified as CO<sub>2</sub><sup>30</sup>) and the CO<sub>2</sub> dissociative decomposition also occurs in Ni interacting with BaO centers that are responsible of the formation of CO and O\* species and is represented as a single reaction [Eq. (12)]. Furthermore, CO<sub>2</sub> reacts with the carbon deposited during the regeneration step by the reverse Boudouard reaction with CO formation [Eq. (11)], which was confirmed with the product distribution of the experiments with unlabeled and labeled CO<sub>2</sub>. During the regeneration step, methane fed reacts with the CO<sub>2</sub> retained over the catalyst on Ni.BaO mixed reduced centers producing H<sub>2</sub> and CO as a bifunctional mechanism of dry reforming of methane indicated in Eqs. (16) and (17). Other reaction that increased CH<sub>4</sub> conversion values above CO<sub>2</sub> conversion values was methane decomposition with carbon and hydrogen formation [Eq. (15)]. The generated H<sub>2</sub>(g) in this stage would promote the reduction of Ni-oxidized catalyst centers, thus regenerating the catalyst and producing water.

The analysis of the results with the isotopic study have led to a scheme that represents the reactions involved in the storage and regeneration stages in the CO<sub>2</sub>-SR technology over NiO.BaO catalyst. It is possible to reach a high CO<sub>2</sub> conversion and the CH<sub>4</sub> catalyst regeneration yielding an enriched syngas stream. A potential syngas production technology based on CO<sub>2</sub> and methane was addressed by the availability of bio-based gas and the demand of technologies for potential utilization of carbon dioxide. The system presented here has a distinctive feature, as a proposal that revalorize methane, the second most harmful fluent gas for the atmosphere, to produce H<sub>2</sub>, as a very efficient energetic vector whose combustion is carbon-free.

## 4. Conclusion

The study in transient regime with labeled molecules has allowed to delve into this novel catalytic technology of the integrated capture of CO<sub>2</sub> and the reaction of CH<sub>4</sub> as alternated pulses cyclic process in a fixed bed reactor configuration using an innovative NiBa unsupported catalyst. The catalyst has a dual functionality, showing a high chemical

Fig. 8. Scheme of the process of cyclic alternated steps of the CO<sub>2</sub> (from combustion) storage and regeneration with CH<sub>4</sub> (from biogas) including the most remarkable reactions involved in CO<sub>2</sub>-SR technology.

retention capacity of CO<sub>2</sub>, with values of 0.8 wt% at 700 °C, comparable to other Dual Material Function-type systems. The regeneration capacity through the injection of methane yielding to H<sub>2</sub>-containing stream production, with H<sub>2</sub>/CO molar ratio between 5 and 25 in the analyzed temperature range. Isotopic tracer study, using <sup>13</sup>CO<sub>2</sub> and CD<sub>4</sub>, validated a mechanistic picture of the reactions network that occur during storage and regeneration alternated cycles and the tentative role of Ni and BaO species on the catalyst surface.

The individualization of stages and the product distribution, with labeled and unlabeled components through three series of experiments, allowed to establish the main reactions involved in the CO<sub>2</sub>-SR process. During the CO<sub>2</sub>-storage stage, conversion and storage values around 8 % were estimated and <sup>13</sup>CO and CO profiles reveal the occurrence of the Boudouard reaction and the consecutive CO<sub>2</sub> adsorption and dissociative decomposition. In the regeneration stage, methane conversion values between 14 and 20 % were obtained in the range of 600–700 °C, with syngas formation via dry reforming and chemical reduction, and the additional methane decomposition causes an increase in the H<sub>2</sub>/CO molar ratio, significantly higher than the stoichiometric value.
